Abstract — **This paper studies nonlinear characteristics of (Boolean) functions which are important in cryptography. Main contributions of this paper are: (1) we show that the restriction of a function on a coset has significant influence on cryptographic properties of the function, (2) we identify relationships between the nonlinearity of a function and the distribution of terms in the polynomial representation of the function, (3) we prove that cycles of odd length in the terms, as well as quadratic terms, in a function play an important role in determining the nonlinearity of the function. Results in this paper will contribute to the study of new cryptanalytic attacks on encryption algorithms, and counter-measures against such attacks.**

I. Motivation and Definitions

In his pioneering work on the theory of secrecy systems [5], Shannon suggested the concept of a "product cipher" which employs a concatenation of several different types of basic transforms. Most modern ciphers have been designed by following Shannon's suggestion. A core component of these ciphers is the so-called S-boxes each of which is mathematically identical to a tuple of nonlinear (Boolean) functions. Recent progress in cryptanalysis, especially the discovery of linear attacks, has highlighted the significance of research into nonlinear characteristics of functions. In this work we focus on the following three nonlinear indicators which have received less extensive studies so far: (1) the restriction of a function to a coset, (2) the distribution of terms, and (3) the hypergraph of a function. We pay special attention to connections between the three indicators and the nonlinearity of a function.

Let V_n be the vector space of n tuples of elements from $GF(2)$. An *affine* function f on V_n is a function from V_n to $GF(2)$ that takes the form of $f(x_1,\ldots,x_n) = a_1x_1 \oplus \cdots \oplus a_nx_n \oplus c$, where $a_j, c \in GF(2)$, $j = 1,2,\ldots,n$. Furthermore f is called a *linear* function if $c = 0$. The *nonlinearity* of f, denoted by N_f, is the minimal Hamming distance between f and all affine functions on V_n, i.e., $N_f = \min_{i=1,2,\ldots,2^{n+1}} d(f,\varphi_i)$ where φ_1, φ_2, ..., $\varphi_{2^{n+1}}$ are all the affine functions on V_n. The nonlinearity of functions on V_n coincides with the covering radius of the first order binary Reed-Muller code $R(1,n)$ of length 2^n [2], and it is upper bounded by $2^{n-1} - 2^{\frac{1}{2}n-1}$ [4]. If $N_f = 2^{n-1} - 2^{\frac{1}{2}n-1}$ then f is called a *bent function* [3]. Bent functions on V_n exist only for even n.

Let f be a function on V_n and U be an s-dimensional subspace of V_n. The *restriction* of f to a coset $\Pi_j = \beta_j \oplus U$, $j = 0,1,\ldots,2^{n-s}-1$, denoted by f_{Π_j}, is a function on U, and it is defined by $f_{\Pi_j}(\alpha) = f(\beta_j \oplus \alpha)$ for every $\alpha \in U$.

II. Main Results

Theorem 1 *Let f be a function on V_n, W be a p-dimensional subspace of V_n, and Π be a coset of W. Then the nonlinearity of f and the nonlinearity of f_Π are related by* $N_f - N_{f_\Pi} \le 2^{n-1} - 2^{p-1}$

Theorem 2 *Let f be a function on V_n, W be a p-dimensional subspace of V_n, and Π be a coset of W. If the restriction of f to Π, f_Π, is an affine function on Π, then the nonlinearity of f, N_f, satisfies $N_f \le 2^{n-1} - 2^{p-1}$.*

Theorem 3 *Let f be a function on V_n and J be a subset of $\{1,\ldots,n\}$ such that f does not contain any term $x_{j_1}\cdots x_{j_t}$ where $t > 1$ and $j_1,\ldots,j_t \in J$. Then the nonlinearity of f, N_f, satisfies $N_f \le 2^{n-1} - 2^{s-1}$ where $s = |J|$.*

Theorem 4 *Let f be a function on V_n and P be a subset of $\{1,\ldots,n\}$ such that for any term $x_{j_1}\cdots x_{j_t}$ with $t > 1$ in f, $\{j_1,\ldots,j_t\} \cap P \ne \emptyset$ holds where $\emptyset$ denotes the empty set. Then the nonlinearity of f, N_f, satisfies $N_f \le 2^{n-1} - 2^{n-p-1}$ where $p = |P|$.*

For a f function on V_n, we define the *hypergraph [1]* of the function, denoted by $\Gamma(f)$, by the following rule: Let $X = \{x_1,\ldots,x_n\}$. A subset of X, $E_j = \{x_{j_1},\ldots,x_{j_t}\}$ is referred to as an edge of $\Gamma(f)$ if and only if $x_{j_1}\cdots x_{j_t}$ is a term of f.

Theorem 5 *Let f be a bent function on V_n. Then either $\Gamma(f)$ contains a cycle of odd length or f contains $\frac{1}{2}n$ disjoint quadratic terms.*

Theorem 6 *Let f be a function on V_n, whose nonlinearity, N_f, satisfies $N_f \ge 2^{n-1} - 2^{\frac{2}{3}n-t-1}$ where t is real with $1 \le t \le \frac{1}{6}n$. Then either $\Gamma(f)$ contains a cycle of odd length or f contains at least $3t$ disjoint quadratic terms.*

Theorem 7 *Let f be a function on V_n, whose nonlinearity, N_f, satisfies $N_f > 2^{n-1} - 2^{\frac{2}{3}n-1}$. Then either $\Gamma(f)$ contains a cycle of odd length or f contains a quadratic term.*
